ABSTRACT

BACKGROUND

Microsurgical lower extremity reconstruction is challenging because of high incidence of vascular thrombosis compared to microsurgical head and neck reconstruction. The risk of vascular pedicle thrombosis increases, if patients have arterial sclerosis or intimal dissection at the recipient artery. We performed selective and continuous transarterial heparin infusion for postoperative anticoagulant therapy.

METHODS

Fifteen patients (10 men and 5 women; mean age of 55.1 years; range of 16–86 years) received lower leg reconstruction using free flap. Postoperatively, a catheter was inserted into the femoral artery during surgery. Heparin infusion was performed through the catheter as a postoperative therapy for patients who had a risk factor of vascular pedicle thrombosis. Until two days post-operation, heparin was started between 5,000 and 10,000 IU per day. In postoperative days 3 and 4, half of the initial dose of heparin was administered. In postoperative days 5 and 6, 25% of the initial dose of heparin was administered.

RESULTS

Recipient arteries were the posterior tibial (n=11), anterior tibial (n=2), lateral circumflex femoral (n=1), and medial sural (n=1) arteries. Thirteen of the 15 cases showed arterial sclerosis or intimal dissection at the recipient artery. There was no case of vascular thrombosis. Hematoma formation at flap recipient was observed in four cases. Their initial heparin dose was than 8.5 ± 1.7 U/kg/h.

CONCLUSION

Continuous transarterial heparin infusion was an effective anticoagulant therapy for the patients who had received free tissue transfer to a lower extremity. The initial dose of heparin should not exceed 6.5 U/kg/h.

INTRODUCTION

Many authors have reported successful reconstruction using the free flap procedure.¹⁻²⁹ The frequency of vascular pedicle thrombosis after free tissue transfer for head and neck region is less than 5%.²⁻⁸ On the other hand, the success rate of lower leg reconstruction using flap is still low.^{1,23-27} Plastic surgeons often perform free tissue transfer to the lower extremities and vascular anastomosis for patients with arterial sclerosis. To avoid vascular pedicle thrombosis, we administered anticoagulant therapy for patients who had arterial sclerosis and received lower extremity reconstruction using free flap.

Vascular thrombosis after free tissue transfer may lead to prolonged hospitalization or delays to starting postoperative rehabilitation. There is no guideline for postoperative therapy for patients who have had arterial sclerosis and received a free tissue transfer for a lower extremity. Heparin infusion is a well-known anticoagulant therapy and some authors reported the effectiveness of heparin infusion as an anticoagulant therapy after free tissue transfer.^{12,13-17,20-22}

To prevent vascular pedicle compromise

in patients whose recipient artery showed arterial sclerosis, we performed continuous and selective transarterial heparin infusion. We were able to prevent postoperative vascular pedicle thrombosis, even where patients showed arterial sclerosis in the lower leg. This report describes the details of our postoperative anticoagulant therapy for patients who had arterial sclerosis or malformation of the recipient artery. We also analyzed the relationship between amount of heparin and bleeding or thrombotic event at the surgical site.

MATERIALS AND METHODS

We retrospectively analyzed the patients' medical records. From April 2008 through December 2018, fifteen patients (10 men and 5 women; mean age=55.1 years; range=16–86 years) received lower leg reconstruction using free flap, with continuous and selective transarterial heparin infusion as a postoperative anticoagulant therapy (Table 1). All surgeries were performed under general anesthesia. After preparation or debridement of the recipient site, flap was harvested and then fixed to the recipient site. Vascular anastomosis was performed under a microscope.

Table 1: Patients profile

No	Age, Sex	Location	Cause	Recon- struction	Recip- ient	Condition of Recipient Artery			Initial dose of heparin (U)
						Vascular malformation	Arterial sclerosis	Intimal dissection	
1	60 M	Thigh	Osteomyelitis	LDMC	LCFA			(+)	8000
2	80 M	Knee	SCC	ALT	MSA		(+)		8000
3	16 M	Lower leg	Ischemia	LDMC	PTA			(+)	10000

15	50 M	Foot	DM	ALT	PTA		(+)		8000

M: Male, F: Female, LDMC: Latissimus dorsi myocutaneous flap, LCFA: Lateral circumflex femoral artery, SCC: Squamous cell carcinoma, ALT: Anterior lateral thigh flap, MSA: Medial sural artery, PTA: Posterior tibial artery, DM: Diabetes Mellitus, DIEP: Diep Inferior Epigastric artery, AVM: Arterial-venous malformation, BCC: Basal Cell Carcinoma

After vascular anastomosis, an incision was made at the femoral region of the affected site. From this incision, a 28G Argyle PI catheter (Covidien, Tokyo, Japan, Figure 1) was inserted into the femoral artery. The tip of catheter was sent to the 10-15cm distal site. Femoral incision was closed using 4-0 Vicryl (Ethicon, Somerville, New Jersey), 4-0 PDS (Ethicon), and 5-0 Ethilon (Ethicon). A catheter was introduced into this wound (Figure 2). Postoperatively, heparin infusion was performed through the catheter.

On the morning of day 2 post-operation, the daily dose of heparin was started at between 5,000 and 10,000 IU. In each of postoperative days 2 and 3, half of the initial dose of heparin was administered. In postoperative days 4 and 5, 25% of the initial dose heparin was administered. In postoperative day 6, heparin infusion was stopped. In postoperative day 8, the catheter was removed (Table 2, Figure 3). The activated partial thromboplastin time (APTT) level was checked every 24 hours until postoperative day seven. Flap survival was evaluated 8 days post-operation. Postoperatively, patients who had bleeding and needed additional treatment (opening of wound or ligation of bleeding vessel) were categorized as severe bleeding complication.

For our patients, differences between preoperative and postoperative APTT were analyzed with the Mann–Whitney U test. Differences in the initial dose of bone heparin between the complication and non-complication groups were also analyzed with the Mann–Whitney U test. The ratios of the postoperative bleeding at flap recipient site between high initial heparin dose (≥ 6.5 U/kg/h) group and low initial heparin dose (≤ 6.4 U/kg/h) group

were evaluated using Fisher's exact test. All calculations were performed using statistical software (SPSS, IBM Japan, Tokyo, Japan), and $p < 0.05$ was considered significant.

RESULTS

The causes of lower extremity reconstruction were Diabetes Mellitus foot ($n=3$), osteomyelitis ($n=2$), malignant tumor ($n=2$), Achilles tendon and soft tissue composite defect ($n=2$), vascular malformation ($n=2$), ulcer due to artery obstruction ($n=1$), scar contracture ($n=1$), and burn ($n=1$). The risk factors for vascular pedicle compromise were arteriosclerosis at the recipient site ($n=7$), intimal dissection ($n=9$), and vascular malformation ($n=2$). Flaps used were anterolateral thigh flap ($n=11$), fibula osteocutaneous flap ($n=1$), latissimus dorsi myocutaneous flap ($n=1$), and deep inferior epigastric artery perforator flap ($n=1$).

Recipient sites were posterior tibial artery ($n=1$), anterior tibial artery ($n=2$), lateral circumflex femoral artery ($n=1$), and medial sural artery ($n=1$). The initial doses of heparin were 10,000 U ($n=5$), 8,000 U ($n=9$), and 5,000 U ($n=1$) (Table 1). The average initial dose of heparin was 6.4 ± 1.8 U/kg/day. Postoperatively, no flap necrosis was observed. On the other hand, severe bleeding from flap recipient site was observed in four cases at 1 day post-operation. The average preoperative APTT value and highest postoperative APTT value were 27.5 ± 10.5 and 27.9 ± 4.6 , respectively. There was no significant difference.

In bleeding patients, preoperative and highest

postoperative APTT values were 28.4 ± 3.4 and 25.8 ± 1.4 , respectively. In non-bleeding patients, preoperative and highest postoperative APTT value was 30.2 ± 8.5 and 28.8 ± 5.3 . There was no significant difference between pre- and post-operative APTT values in either bleeding patients ($p=0.149$) or non-bleeding patients ($p=0.859$). The average initial heparin dose among patients who had severe postoperative bleeding was 8.5 ± 1.7 U/kg/h.

On the other hand, the average initial heparin dose among non-bleeding patients was 5.9 ± 0.56 U/kg/h. The initial dose of heparin per body weight was significantly higher than bleeding patients ($p=0.035$, Table 3). We divided our patients into two groups (HD; initial dose heparin ≥ 6.50 U/kg/h, LD; initial dose heparin ≤ 6.49 U/kg/h). In the HD group, three of the four patients had a bleeding complication. On the other hand, in the LD group, one of the nine patients had a bleeding complication. The rate of postoperative bleeding in the HD group was significantly higher than that of the LD group ($p=0.041$, Table 3).

DISCUSSION

Free flap is a useful surgical procedure for the reconstruction of wide and complex tissue defects. In cases of vascular pedicle thrombosis, re-exploration is required. Re-exploration may lead to prolonged hospitalization. Various anticoagulant therapies after microsurgery have been reported.⁸⁻²⁰ Heparin is one of the most popular drugs for anticoagulant therapy after microsurgery.^{12,15,20} To perform effective post-anticoagulant therapy, high-concentration anticoagulant drugs should be delivered for vascular pedicle. Ashjian et al. compared effectiveness between 325 mg/day of aspirin and 5000 U/day heparin infusion.¹⁴

They found no significant differences between effectiveness of aspirin and heparin. Khouri et al. examined 493 free flap transfers and compared effectiveness among various postoperative anticoagulant therapies.¹ They concluded that only postoperative subcutaneous heparin injection could decrease rate of flap failure. Some authors reported that post-microsurgical anticoagulant therapy does not decrease the risk of vascular pedicle compromise. However, in their report, most of their cases were head and neck reconstruction cases.^{8,9}

The rate of free flap failure among patients who underwent head and neck reconstruction using free flap was only 0–5%, even without anticoagulant therapy after microsurgery.^{2–7} These results suggest that it is very difficult to further decrease risk of free flap failure. However, the rate of free flap failure after lower leg reconstruction remains high.^{23–27} Intraoperatively, we sometimes experience cases who have recipient artery with arterial sclerosis or dissection of intima.

We felt the need for post-microsurgical anticoagulant therapy in these cases. We used heparin via catheter inserted into the femoral artery. From the survey by Xipoleas et al., two of 102 microsurgeons performed systemic venous 5000 U/day heparin infusion until 1 day after free tissue transfer to the lower extremity.²⁶ Eley et al. also performed 2,500–10,000 U/day systemic low molecular weight heparin infusion after free flap transfer.¹¹ From these results, using heparin 10,000 U/day causes less than 2.3% hematoma formation.

We believe this dose of heparin is not effective. Based on the 2014 European Society of Cardiology guideline, more than 18 U/kg/h heparin is required to keep 1.5 to 2.3 times higher APTT value than normal.³⁰ The average body weight of our patients was 55.1±18.7 kg. From the guideline, about 23,000 U/day heparin should be administered considering this average weight. However, if we use such high doses of systemic heparin infusion, postoperative hematoma or bleeding may cause.

To send high-concentration heparin for vascular pedicle without hematoma formation or bleeding, some authors perform local transarterial heparin infusion. Fukui et al. reported 240,000 U of urokinase, 40 µg PGE1, low molecular weight dextran, and 10,000 U of heparin were administered until 10 days postoperatively.²⁸ Saito et al. also performed transarterial heparin infusion. In their report, 2,000 U daily heparin with 40 µg PGE1 were administered until one week post-operation.²⁹

On the other hand, we used an initial heparin dosage of 10,000–5,000 U. None of our cases showed increased APTT value. However, no vascular thrombosis was observed. Some authors reported that the most common reason for free flap failure after lower leg reconstruction was vein thrombosis.^{22,31} To send heparin to the anastomotic site of the vein, the catheter should

be inserted into the flap vein. However, it is very difficult to insert catheter to flap vein. In our study, four cases showed bleeding from surgical site. This result suggests that we could send high-concentration heparin for vascular pedicle of flap without inserting catheter for flap vein.

CONFLICT OF INTEREST

The authors declare no conflict of interest.
